Code, data and every trial log: https://github.com/fe2131-art/rescue-mind

This document holds material moved out of the main paper. Section, table and figure numbers with an S prefix refer to this document; unprefixed references are to the main paper. All numbers are generated from the same result files as the main paper. It is organised as follows. *Methods and background:* S1 development data, T1 construction and the two-model rule; S2 model selection on development data; S3 the extended related work. *Results:* S4 additional T1 analyses (decision-rule ablations, risk–coverage, weaker models); S5 campaign E details; S6 wall-clock timing; S7 further result details (studies Z, P, R, campaigns F, G and H, hazard fixes). *Failure analysis:* S8 lessons from running the real stack. *Audit:* S9 the registration audit and threats to validity. *Moved from the main paper:* S10 untrusted inputs (proof of Proposition 2, cost bound, threat model); S11 the second checker and campaign J.

S1. Development Data, T1 Construction and the Two-Model Rule

Development data. Prompts, the scoring method, thresholds and model choice were selected on 176 development images. These are 48 with randomised viewpoints plus 128 with lighting presets, a cardboard-box distractor and fire. The instruction parser was tuned on 40 development utterances. The later hazard fixes (main paper, Sec. V-C) also used two hazard development sets of 300 rendered images each: DH, and DH2, which emphasises small early-stage fires.

Two-model rule. The two-model rule (Sec. S11) approves only if Eq. (1) holds for Qwen *and* Clef-Flash names the requested supply with confidence ≥ 0.65, presence ≥ 0.80 and hazard probability below its own threshold.

T1 examples. Fig. S1 shows held-out T1 images. T1 used 60 Gazebo worlds $\times$ 2 stations $\times$ 5 viewpoints with continuous random lighting, supplies moved by up to ± 0.15 m and freely rotated, random fire positions, and three distractors. Two of the distractors never appeared during development: a blue crate and an orange traffic cone (orange but not fire).

S2. Model Selection on Development Data

Models were ranked lexicographically. The first key was zero false approvals and zero unsafe intent acceptances, and the second was explanation and intent accuracy. Qwen3-VL-8B parsed more development utterances but accepted two unsafe ones. Qwen3.5-4B produced a false approval. Qwen3.5-9B was therefore chosen and frozen before the T1 and E registrations.

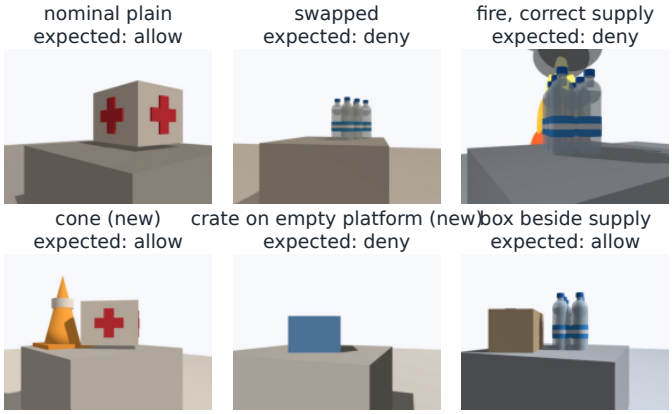

Fig. S1. Held-out T1 images (robot camera, 640×480) with the generator's expected decision. The crate and the traffic cone never appeared during development.

TABLE S1
Candidate models with the final prompts (`v35`: checkpoint questions of v3.5; `i35`: instruction parser) on development data only. Images: correct decisions with false approvals (FA) and false denials (FD). Explanations: one-sentence reports judged correct against the generator labels. Intent: development utterances, with unsafe acceptances. VRAM in MiB.

Model	Released	Images (176)	Explanations (128)	Intent dev (40)	VRAM
Qwen2.5-VL-3B	2025-01	176/176 (FA 0/FD 0)	84/128	31/40, unsafe 0	–
Qwen3-VL-8B	2025-10	176/176 (FA 0/FD 0)	120/128	38/40, unsafe 2	17212
Qwen3.5-4B	2026-02	175/176 (FA 1/FD 0)	125/128	35/40, unsafe 2	9102
Qwen3.5-9B	2026-02	176/176 (FA 0/FD 0)	125/128	35/40, unsafe 0	18320

S3. Extended Related Work

The main paper condenses this section; the full text follows.

Failure detection and verification with foundation models. REFLECT [1] and AHA [2] explain manipulation failures in natural language after the fact. Inner Monologue [3] feeds success detection back into a planner. Du et al. [4]

fine-tune a VLM as a success detector. Sentinel [5], FAIL-Detect [6] and FIPER [7] monitor learned policies at run time (FIPER calibrates its out-of-distribution and uncertainty scores conformally on successful rollouts and requires both signals to alarm); Code-as-Monitor [8] checks task constraints with VLM-generated programs, both reactively and proactively, without a calibrated threshold or a ground-truth audit; an LLM-based anomaly monitor triggers reactive fallbacks [9]; and uncertainty-aware policy steering decides when to act, ask or learn [10]. *Closest prior art.* VAP-TAMP [11] (arXiv preprint, April 2026; we read the full text) verifies the preconditions and effects of each PDDL action with a VLM. For each predicate it generates several semantically equivalent yes/no questions, takes a majority vote and, if the answers agree, asks the VLM whether the view is sufficient; otherwise the VLM proposes a viewing direction and the robot moves there, up to a viewpoint budget. A failed verification corrects the scene graph and triggers PDDL replanning. It was evaluated by task success on 100 real mobile-manipulation trials and on injected failures in OmniGibson. The overlap with our design is real: paraphrase agreement is the counterpart of our permuted-question agreement, and VLM-chosen views are the counterpart of our look-around. To our knowledge, the differences are (i) our scores are next-token probabilities over a closed answer set with a threshold calibrated on development data, whereas VAP-TAMP uses textual yes/no answers and a vote; (ii) in our design every check is combined in a fail-closed conjunction, so a failed check or an extra view can only refuse or revoke, whereas in VAP-TAMP a verification result corrects the symbolic state in either direction; (iii) an independent velocity guard that the VLM cannot command; (iv) memory that may only reorder checks and add caution; and (v) pre-registered closed-loop audits of the error direction against simulator ground truth, which report the unsafe-delivery rate and not task success. VAP-TAMP covers things we do not: PDDL task and motion planning, manipulation, and real-robot trials. Semantic anomaly detection with LLMs [12] and visual question answering that abstains rather than answers wrongly [13] are close in spirit to a gate that prefers refusal. Our check runs *before* the robot acts and is closed-set and zero-shot. Its output is a thresholded accept/reject that is audited against simulator ground truth. The closest methodological relative is KnowNo [14], which scores multiple-choice answers by next-token probability and asks a human for help, with a conformal-prediction coverage guarantee (see [15] for background on conformal prediction). Introspective planning [16] extends this line by letting the planner reason about task ambiguity. Conformal risk control [17] controls the expected value of any monotone loss (for example a false-negative rate), and Learn then Test [18] gives high-probability risk control; our study K (held-out fire miss rate $\leq \alpha$ with probability 0.9) is of that form. Conformal decision theory [19] calibrates a robot decision rather than a prediction set. Our gate is a one-shot accept/refuse threshold and not an online-adaptive controller. SayCan [20] likewise scores a fixed candidate set by language-model likelihood. We share the scoring, but we respond to uncertainty by refusing or searching, and we add permuted-option agreement as a test-time defence against letter bias.

Multiple-choice scoring and its biases. Scoring answer symbols works well when a model binds symbols to options [21]. Language models are reasonably calibrated on well-formatted multiple-choice questions [22], but they prefer certain option IDs [23] and orders [24], and their raw confidence needs validation [25], [26]. On embodied question answering, even the best frontier model reaches only 42.79% recall when it should abstain [27], which supports a calibrated refuse option over trusting the model to abstain. Our two permuted questions are a minimal, deterministic form of self-consistency [28]. The Yes/No hazard question follows the polling style of POPE [29].

Safety architectures. Simplex [30], [31], shields [32] and control barrier functions [33] keep a simple verified layer between a complex decision maker and the actuators. LLM-controlled robots can be manipulated into harmful actions [34], and guardrails such as RoboGuard [35] check plans before execution. The safety filter [36] is the current umbrella for such least-restrictive overrides of a nominal controller; our velocity guard is a minimal instance and the VLM check is a perception-side gate in the same spirit. Closest in using a VLM for safety, Santos et al. [37] turn images and language feedback into a failure set that a Hamilton–Jacobi safety filter enforces, so the guarantee comes from the verified filter; ours is a union bound over check errors. RoboSafe [38] guards VLM-driven embodied agents with executable safety rules and a short- and long-term safety memory, which drives rule-based replanning and is not constrained to be safety-monotone. In contrast to vision-language-action models [39], [40], our VLM never commands motion.

Memory for robots in changing environments. Robots increasingly keep long-horizon semantic memory. ReMEmbR [41] and Embodied-RAG [42] retrieve from a database of captioned observations; KARMA [43] adds long- and short-term memory to embodied agents, and H-EMV [44] verbalises a robot's episodic memory. 3D scene graphs such as Hydra [45], ConceptGraphs [46] and HOV-SG [47] support planning [48] and language grounding [49]. Long-term mapping has long dealt with change [50], [51], and recent work tracks changes in dynamic scene graphs [52], [53]. These systems use memory to *answer* or *plan*. A recent preprint reports, in a small grid-navigation testbed, that acting on unaudited stale memory can be worse than having no memory [54]. Long-term agent memory is also an attack surface: corrupted entries can steer an LLM agent [55] (an LLM-agent result, not a robotics one). Memory benchmarks such as FindingDory [56] measure how well memory supports recall in long-horizon tasks, not whether acting on it is safe once the world has changed. GLOVE [57] and VLM-DEWM [58] check memory or a world model against fresh observations to keep the memory *correct*.

Object search with priors and semi-static maps. Using past observations to decide where to look first is a classic idea, and we do not claim it as ours. Active visual ob-

ject search keeps a belief over target locations and plans where to look next, using uncertain spatial and semantic knowledge [59], inter-object relations in Semantic Linking Maps [60], or object-oriented POMDPs whose belief factorises over objects [61]. Long-term mapping models objects or features that persist, appear or disappear (semi-static) and detects change [62], [63]; DovSG updates an open-vocabulary 3D scene graph locally as objects are moved [64]. Zero-shot object navigation with language or vision-language priors, such as ESC [65] and VLFM [66], uses a pre-trained model as a prior over where to explore, but has no mission-to-mission memory of a specific site. To our knowledge, these works optimise search efficiency (path length, success rate, map accuracy) and treat a detection, or an updated map, as the basis for the next action. We did not find in them a bound on the unsafe-action risk caused by *stale* memory at a pre-action gate. Our memory is narrower and serves a different goal: it may only reorder stations and add caution, the on-site verification is never skipped or relaxed, and this restriction is enforced in code and checked by the run audit, which gives a union bound that does not depend on how old the memory is. These methods could supply the ordering prior in our setting, for example a belief over supply location, provided the gate stays unchanged; combining them is future work, and we have not compared search efficiency against them. We study a different use: memory decides *where and how carefully to verify*. We restrict it so that it can never reduce verification, and we state this as a provable invariant and test it under scripted change.

Active perception. Moving the sensor to resolve ambiguity is a classic idea [67], [68], and view planning for inspection is well studied [69]. Recent embodied agents explore until a VLM is confident [70] or let a VLM choose views [71]. Our look-around is deliberately simple: two fixed side views, used only to *revoke* an approval. This makes its effect auditable and its safety direction obvious.

Robustness and the sim-to-real gap. Image classifiers degrade under common corruptions [72], and so do detectors [73], adapted vision-language models [74] and video-language models [75]. Sim-to-real transfer is a recognised challenge in robotics [76]. Without a physical platform, we measure one part of this gap, sensor degradation, under a pre-registered protocol. What we care about is the *direction* of the errors, not only accuracy.

a) Untrusted inputs to embodied agents.: Jailbreaks of LLM-controlled robots are now well documented: RoboPAIR [34], BadRobot [77], the policy-executable attacks of Lu et al. [78] and adversarial text attacks on vision-language-action models [79] all steer the planner through the instruction channel. A second line puts the payload in the scene: signs and printed text in the camera view hijack VLM-controlled robots [80], [81], and sensory channels (OCR, audio, LiDAR) inject prompts into ROS 2 robots [82]; typographic vulnerability of large vision-language models [83] and indirect prompt injection in LLM-integrated applications [84] are the underlying mechanisms. Memory is a third channel: poisoned or injected memory entries steer LLM agents [55], [85], and a recent survey lists long-term memory and multi-agent communication as under-explored attack surfaces of embodied agents [86]. Defences in robotics are mostly filters or certification of the plan: RoboGuard grounds rules in a root-of-trust LLM and checks plans against them [35], and the mitigations proposed alongside the attacks are prompt defences, two-stage verification and text masking [78], [81]. The closest conceptual relatives are structural defences for software agents: CaMeL separates control and data flow and attaches capabilities to tool calls [87], and information-flow control labels the integrity of inputs and enforces policy deterministically [88]. We carry this idea to a physical pre-action gate: advice from memory, peer robots, inventory and operator text is typed so that it can only reorder visits or tighten thresholds, never skip or relax a check, which yields a bound on unsafe deliveries that holds for any advice (advice monotonicity) and is evaluated closed-loop against poisoned memory and injected instructions (study A). Text in the scene is perception, not advice, and so lies outside this guarantee; we measure it separately (study S) and report the residual vulnerability.

TABLE S2
T1 HELD-OUT TEST, REGISTERED V3.4 RULE (EQ. **??**) UNLESS MARKED FREE JSON; 408 MUST-REFUSE AND 191 MUST-APPROVE IMAGES.

Model	False approvals	Correct approvals	Hazard recall	Cone alarms	s/pass
Qwen3.5-9B	5/408	187/191	67/76	0/25	0.98
Qwen3.5-4B	9/408	190/191	59/76	0/25	1.06
Qwen3-VL-8B	4/408	183/191	68/76	0/25	0.46
Qwen2.5-VL-3B	4/408	187/191	68/76	0/25	0.83
Qwen3.5-9B (free JSON)	5/408	158/191	–	–	–
Qwen2.5-VL-3B (free JSON)	0/408	57/191	–	–	–

Diverse redundancy. Requiring agreement between independently developed versions is a classic fault-tolerance technique [89]. Its benefit is limited by correlated failures [90], and model-agreement schemes for language models have reappeared recently [91]. We report both sides: the two models agree on most images, and the second model's value depends strongly on how it is asked.

Evaluation practice. We follow recommendations to report conditions, multiple metrics, uncertainty and failure modes [92]. We use Wilson intervals [93] and exact McNemar tests [94]. Domain randomisation [95] is used here to build a held-out *test* distribution, not for training. Our design is fixed-n and pre-registered; sequential testing with valid early stopping [96] is a possible refinement for small n. How far simulation predicts real-world behaviour is itself measurable [97]; we make no claim beyond simulation.

Fire and smoke perception. We use D-Fire [98] for study P because it is CC0 and ground-level with negative images; FASDD [99] is a larger alternative with ground-level, UAV and satellite subsets and a possible future source. Local open-weight VLMs have been used for wildfire detection from UAV imagery [100], descriptively and without refusal semantics or a closed-loop audit.

TABLE S3
DECISION-RULE ABLATIONS ON T1: FALSE APPROVALS / FALSE DENIALS. *: EXACT MCNEMAR $p < 0.05$ VERSUS THE FULL RULE OF THE SAME MODEL.

Decision rule	Qwen3.5-9B	Qwen3.5-4B	Qwen3-VL-8B	Qwen2.5-VL-3B
Full rule	5 / 4	9 / 1	4 / 8	4 / 4
A1: question 1 only	5 / 4	9 / 0	4 / 7	4 / 4
A2: question 2 only	5 / 1	9 / 1	4 / 2*	36 / 1*
A3: no hazard question	47 / 4*	48 / 1*	46 / 8*	48 / 4*
A4: no threshold (τ_s=0)	5 / 4	9 / 1	4 / 8	4 / 4
v3.5: τ_h=0.05 (I-10)	3 / 4	4 / 1	4 / 8	1 / 30*

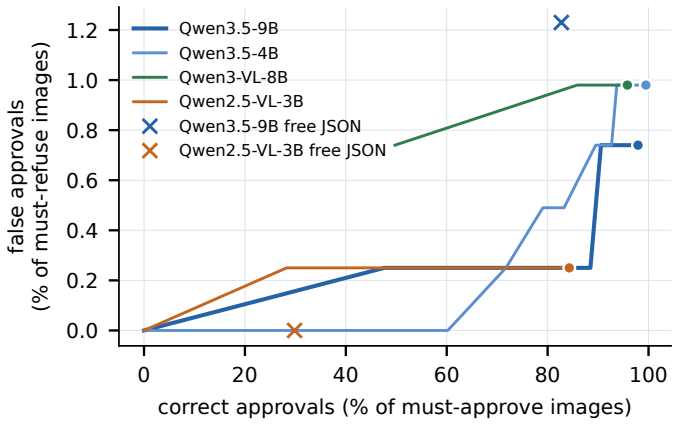

Fig. S2. T1 risk–coverage: false-approval rate versus correct-approval rate as τ_s varies ($\tau_h = 0.05$, v3.5). Markers show the frozen $\tau_s = 0.5$. The curves are flat over most of the range: the remaining errors are missed fires, which τ_s cannot fix.

S4. ADDITIONAL T1 ANALYSES

Free-form generation. Free JSON (A5) gave no parse errors with Qwen3.5-9B and the same 5 false approvals, but only 158 correct approvals against 187 with scoring. All models missed largely the same small fires (hazard recall 59 to 68 of the 76 visible fires); Supp. Fig. S2 shows descriptive risk–coverage curves over τ_s.

A. Decision-rule ablations

Table S3 isolates the parts of the rule on T1 (Table S2, Eq. 1 of the main paper). For the 9B model neither the permuted second question nor the confidence threshold changed the number of false approvals. With Qwen2.5-VL-3B, requiring the two multiple-choice questions to agree reduced false approvals, which is the option-letter bias reported in [23].

B. Risk–coverage

Fig. S2 varies τ_s only for description, because τ_s was not tuned on T1.

C. Weaker models and free-form output

For Qwen2.5-VL-3B the second question alone approved 36 must-refuse images, and requiring agreement with the first question brought this down to 4, which is the option-letter bias reported in [23] in action (Table S3). Asking this model for free JSON (A5) left 148 of the 1200 generations unparseable and approved 57 images; Qwen3.5-9B gave no parse errors (main paper, Sec. V).

TABLE S4

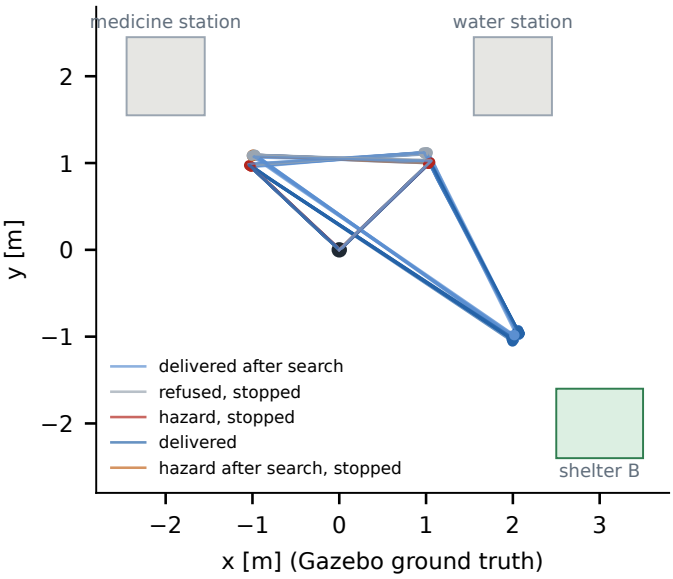

Fig. S3. Campaign E: ground-truth trajectories of all final trials, coloured by audited outcome.

S5. CAMPAIGN E DETAILS

Campaign E used a new randomised world in every trial (main paper, Sec. V); Table S4 gives the outcomes by stratum and Fig. S3 the ground-truth trajectories.

S6. WALL-CLOCK TIMING

Where the time goes. Table S5 breaks down the 34 delivered missions that needed no search. The check itself takes about 5.5 s: aiming, waiting until stationary, frame checks, and the scored VLM queries (3.4 s). Driving between station and shelter takes about 39 s (sum of phase medians). The check is therefore short compared with driving. The situation report adds about 5 s but could run in parallel with the drive to the shelter.

S7. FURTHER RESULT DETAILS

Real photographs (studies P and P2; full text moved from the main paper). We also asked the frozen v3.6 hazard question about 400 real photographs from the test split of D-Fire [98], a CC0 fire and smoke dataset (100 each with no fire, smoke only, fire only, and both). It flagged 298/300 of

TABLE S5
WALL-CLOCK PHASES OF DELIVERED MISSIONS WITHOUT SEARCH (CAMPAIGNS D AND E; V3.4 AND V3.5, NO LOOK-AROUND).

Phase	Median [s]	Min	Max
drive to station	14.31	12.19	16.62
aim camera	0.50	0.50	0.52
wait until stationary	0.67	0.66	0.71
acquire and check frames	0.90	0.75	0.98
VLM decision (scored queries)	3.44	2.95	6.64
situation report (not used to decide)	5.14	3.99	8.54
drive to shelter	24.83	15.02	25.32

TABLE S6
STUDY Z: ZERO-SHOT CONTRASTIVE BASELINES VERSUS OUR CHECK ON THE HELD-OUT SETS (FALSE APPROVALS / CORRECT APPROVALS).

System	T1 FA	T1 CA	T2 FA	T2 CA
Ours (T1 v3.5, T2 v3.6)	3/408 (0.7%) [0.2, 2.1]	187/191 (97.9%) [94.7, 99.2]	0/407 (0.0%) [0.0, 0.9]	190/193 (98.4%) [95.5, 99.5]
SigLIP (so400m, zero-shot)	44/408 (10.8%) [8.1, 14.2]	191/191 (100.0%) [98.0, 100.0]	47/407 (11.5%) [8.8, 15.0]	193/193 (100.0%) [98.0, 100.0]
CLIP (ViT-L/14, zero-shot)	0/408 (0.0%) [0.0, 0.9]	2/191 (1.0%) [0.3, 3.7]	0/407 (0.0%) [0.0, 0.9]	0/193 (0.0%) [0.0, 1.9]

the photographs with fire or smoke (95% CI [97.6, 99.8]%) and 64/100 of the fire-free ones ([54, 73]%); the false alarms concentrate on hard negatives such as hazy hillsides and sunset clouds (Supp. Sec. S7). The probabilities still rank the photographs well (AUROC 0.96, not registered), so the problem is the threshold, not the question. The question thus errs strongly toward stopping on real images, which is the safe direction but would cost availability outdoors, so a site-specific threshold calibration is a deployment prerequisite. Study P2 tested this: it chose wording and τ_h on 400 separate calibration photographs (recall ≥ 0.95 first, then the lower false-alarm rate), with wording **TBD** and τ_h = **TBD**, and applied it to 400 test photographs. It flagged **TBD** of those with fire or smoke (**TBD**) and **TBD** of the fire-free ones (**TBD**), against **TBD** and **TBD** for the frozen $\tau_h = 0.05$. The registered claim (test recall ≥ 0.90 and false-alarm rate ≤ 0.20) was **TBD**.

Conformal τ_h (study K, moved from the main paper). Split-conformal calibration of τ_h on 211 development fires (miss rate $\leq \alpha$ with probability 0.9) gave $\tau_h = 0.0050$ ($\alpha = 0.05$) and 0.0113 ($\alpha = 0.10$). On the 76 visible T2 fires the bound held at $\alpha = 0.05$ and held at 0.10 (0/76 and 0/76 missed), with 26/193 and 4/193 false alarms on 193 fire-free must-approve images, against 0/76 and 0/193 for the frozen $\tau_h = 0.05$. Exchangeability is broken by design (small fires: 27% of calibration, 7% of T2 fires); the frozen threshold was not changed.

Instruction parsing (moved from the main paper). On 60 held-out utterances the hybrid parser was correct for 55/60 with 0 unsafe acceptances (TF-IDF parser: 31/60, 2 unsafe); all five errors were refusals, so they fail closed.

Study Z. The contrastive baselines used SigLIP [101] and CLIP [102] prompts for the supply and the hazard, and the same crops as our check. On development data no threshold pair gave both few false approvals and many correct ones. The contrastive scores do not separate "right supply, no fire" from the alternatives in these scenes.

T1 hazard-question false alarms. With the registered v3.4 rule, the hazard question raised false alarms on 0/25 traffic-cone images and on 0/523 images without fire. With the v3.5 rule, it raised false alarms on 0/25 cone and 0/523 fire-free images.

TABLE S7
STUDY R: V3.6 OFFLINE CHECK UNDER CAMERA DEGRADATIONS (T2 SUBSET). SEVERITY M = MODERATE, S = SEVERE.

Degradation	Sev.	False appr.	Fire missed	Correct appr.	Gate rej.
None (clean)	–	0/192	0/27	107/108	0
Sensor noise	M	0/192	0/27	107/108	0
Sensor noise	S	0/192	0/27	107/108	0
Motion blur	M	0/192	0/27	106/108	0
Motion blur	S	0/192	0/27	101/108	0
Defocus	M	0/192	0/27	108/108	0
Defocus	S	0/192	0/27	108/108	0
Under-exposure	M	0/192	0/27	107/108	0
Under-exposure	S	0/192	0/27	106/108	0
Over-exposure	M	0/192	0/27	96/108	4
Over-exposure	S	0/192	0/27	59/108	24
JPEG	M	0/192	0/27	108/108	0
JPEG	S	0/192	0/27	107/108	0

Campaign F, remaining misses. Six of v3.6's seven remaining misses were fires of 1 100–2 400 visible pixels with hazard probabilities of 0.002–0.006, which overlap those of fire-free views, so no threshold can separate them. The seventh showed 8 600 pixels at $p_h = 0.019$.

Campaign G, world set and medians. The set of worlds is defined from mask renders at all three views, so it includes the side views by construction. The medians over all delivered runs, 102 s and 122 s, are not comparable, because look-around refused most of the fire runs that the front-only system delivered.

Study P, false alarms and licence. D-Fire [98] was released by its authors under CC0, as stated in the original repository's LICENSE; we used a Hugging Face mirror. Rendered fire is stylised, which motivated this check on real photographs. D-Fire's fire-free class comes from fire-surveillance cameras and is rich in hard negatives: hazy hillsides, low clouds, a smudge on the lens, red sunset clouds, glowing tents. Everyday scenes such as streets, beaches and roads scored $p_h \approx 0.01$. The question was worded to catch faint smoke ("a grey or black cloud") and thresholded at 0.05, so it errs strongly toward stopping on real images. We registered the site-specific threshold calibration as a follow-up study (P2).

Campaign H, failure types. Staleness predicts two failure types for naive memory: delivering a supply that has been moved away, and delivering where a fire has appeared since the last visit; the per-trial ledger records which occurred.

Study R, all conditions. Table S7 gives the false approvals, correct approvals and acquisition-gate rejections of study R (main paper, Sec. V-D) for every degradation and severity.

Hazard fixes on development data. Table S8 compares the candidate hazard fixes of the main paper (Sec. V-C).

Campaign H, per-mission outcomes. Fig. S5 shows every mission of campaign H (main paper, Sec. V-E).

Campaign H, case study. Fig. S6 shows the one mission in which M0 delivered into a fire (sequence Q09, mission 3).

Memory caution versus a global threshold (descriptive,

Fig. S4. Study R: one held-out frame with a visible fire under the six registered degradations (severe level; the moderate level is milder). Over-exposure washes out the flames in this example. Frames that the acquisition gate rejects count as refusals.

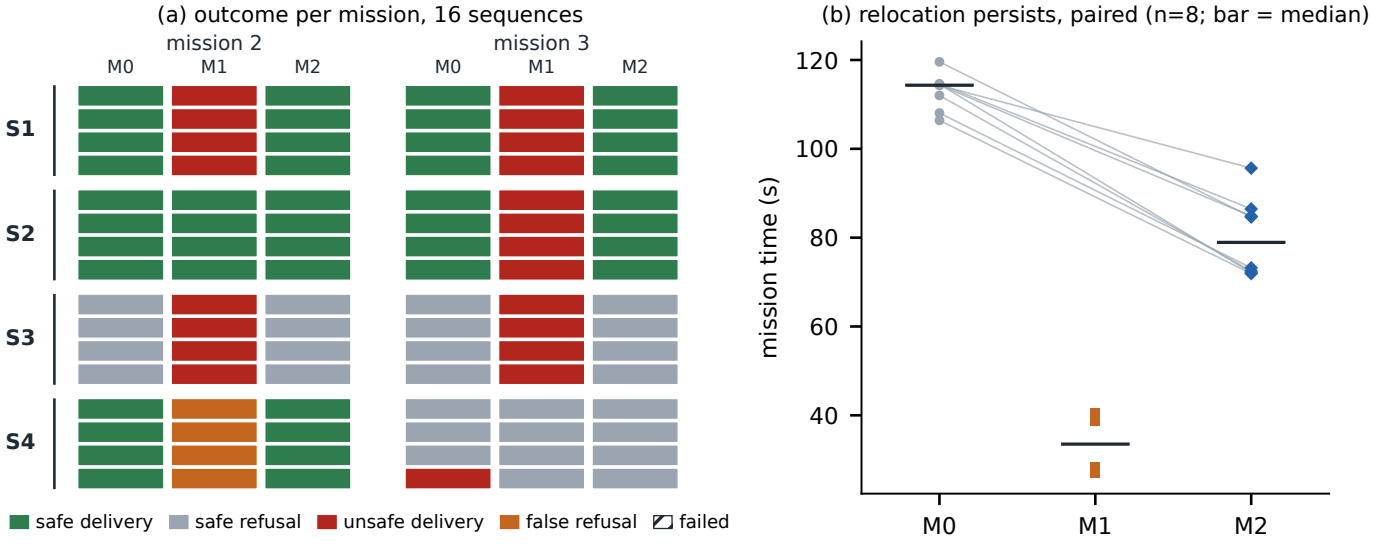

Fig. S5. Campaign H, missions 2 and 3 of the 16 sequences. (a) Outcome of each mission under no memory (M0), naive memory (M1) and verified memory (M2); rows are sequences, grouped by scripted story (S1–S4; definitions in the caption of Table S8). No mission failed (the hatched "failed" category is empty). (b) Mission time of the eight missions whose relocation persisted, for each arm; grey lines join the M0 and M2 times of the same mission, bars mark medians. M1 times are short because M1 skips the checks.

TABLE S8
HAZARD FIXES ON DEVELOPMENT DATA (DEV V1+V2, DH, DH2). $\tau_h = 0.05$ UNLESS STATED.

Configuration	False appr.	Correct appr.	Fires refused	One V100
v3.5: Qwen3.5-9B	46/413	357/360	165/211	yes

TABLE S9
SECOND-MODEL OVERLAP ON THE 211 VISIBLE FIRES OF THE DEVELOPMENT SETS DH AND DH2 (NO TEST DATA). A FIRE IS MISSED WHEN THE CHECKER WOULD APPROVE THE VIEW (QWEN3.5-9B V3.6, $\tau_h = 0.05$; CLEF-FLASH WITH TASK WORDING, HAZARD THRESHOLD 0.05; SAME RULES AS TABLE S8). SCRIPT: `SCRIPTS/JEV_OVERLAP.PY`.

	Clef-Flash misses	Clef-Flash catches
Qwen misses	15	2
Qwen catches	27	167

Qwen misses 17, Clef misses 42; P(Clef misses | Qwen misses) = 88% (Wilson [66, 97]%); Jaccard 0.34. Counting only the hazard question (probability ≥ 0.05 in the hazard question alone): Qwen misses 23, Clef misses 55, both miss 23.

not registered). Campaign H stored decisions, not every view's p_h, so only a partial comparison is possible from existing logs. *Fires:* the one mission where caution changed an outcome is Q09.3 (M0 $p_h = 0.035$, M2 0.049); a global $\tau_h = 0.0113$ (study K, $\alpha = 0.10$) would have stopped M0 there too, since $0.035 > 0.0113$. *False stops:* on the 193 fire-free T2 views the global $\tau_h = 0.0113$ gave 4/193 false alarms (2.1% per view, about 6% per approval with three views if independent), against 0/193 at the deployed 0.05. Caution applied in 12 of the 32 M2 missions: 8 at stations with a fire (all 8 stopped) and 4 at fire-free stations, with 0 false refusals there (Wilson upper bound 49%). That is compatible with both zero and the global rate, so a comparison at equal false-stop rate cannot be made from these logs. What caution does buy by construction is lower exposure: the strict threshold applies at stations with a recent hazard, not everywhere. A direct test needs many fire-free missions at stations with a hazard history; we did not run one.

A. Campaign H: all paired missions

Table S8 lists every paired mission of campaign H (missions 2 and 3 of the 16 sequences) with its outcome and mission time under M0, M1 and M2.

Repeated-mission model. The model of repeated missions, with the per-check rates measured in G and H ($p_{\text{det}} = 0.95$, $n = 44$), is shown in Fig. 4 of the main paper (Sec. V-E); its curves are computed from measured rates, so their order is a

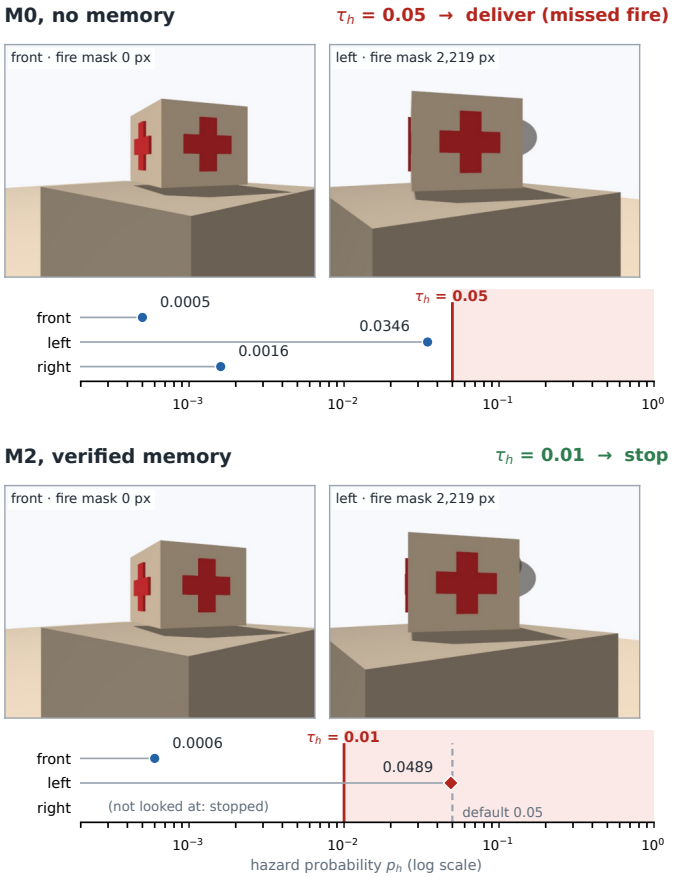

Fig. S6. Cross-mission memory (I-15), campaign H, sequence Q09 mission 3: the same world without memory (M0) and with verified memory (M2). Each row shows the front view and the left side view (fire-mask pixels from the simulator) and the hazard probability p_h of every view that was checked against the threshold (shaded: $p_h \geq \tau_h$). M0 used $\tau_h = 0.05$; the left view scored 0.035 and the robot delivered. M2 had seen a fire at this station two missions earlier, so it used $\tau_h = 0.01$; the left view scored 0.049 and the robot stopped without checking the right side. The fire is small and partly hidden from the left, so the two p_h values are close.

model prediction, not an observation. The figure also shows a fourth policy, M1age, a naive memory that is trusted only while its entry is recent (recency-gated, without verification); it lies between M1 and M2 in unsafe deliveries. Over the whole range of change probabilities $q \in [0, 0.5]$ the model finds no break-even point: M1 and M1age stay faster than M0, and M2 is faster than M0 at small q and converges to it as q grows, because M2 re-checks and so approaches the no-memory behaviour. At $q = 0.2$ per mission the unsafe deliveries per 100 missions are 35.83 for M1, 1.95 for M2 and 1.95 for M0, with mean mission times 32.4, 71.7 and 80.3 s. Neither the single missed-fire delivery nor the 32 paired missions measure how often a real world changes; q is a free parameter of the model.

More stations (descriptive, not registered). Our arena has $k = 2$ stations, so memory can save at most one search detour. Let the supply sit at one of k stations and move, with probability q between missions, to a uniformly chosen other station, so its long-run location is uniform. Without memory the robot visits stations in inventory order and needs $(k+1)/2$ visits on average; with verified memory it first visits the station where it last saw the supply and needs $1 + qk/2$. With the detour $\delta = 30$ s measured in H, the expected saving is $\delta\,((k-1) - qk)/2$ per mission and vanishes at $q^* = (k-1)/k$. For $k = 2$ this reproduces the Monte-Carlo model above (9 s at $q = 0.2$); for $k = 8$ it is 80 s. A simulation of the same process agrees within 1 s for $q > 0$ (`scripts/h_k_scaling.py`). The safety side does not depend on k in this way: each policy checks every station it delivers from with the same rule, so Corollary 1 applies unchanged, and memory lowers the expected number of checks per mission rather than their strength. The model assumes the stations are equally far apart and that supply identification is perfect (T1: no supply false approvals in 332 images).

S8. Failure Analysis and Lessons

Running the full stack on a GPU revealed 23 problems that 620 offline unit tests and mocked ROS runs had not; the most instructive are listed here (the full table is in `docs/FINDINGS.md` in the repository).

- **The auditor trusted the controller's sensor.** The wheel joint axis was expressed in the child-link frame after a 90° roll, so the wheels spun about the vertical axis. Odometry reported 1.5 m forward motion while the body slid sideways by 0.75 m. An audit based on `/odom` would have passed the run. Audits now use Gazebo's ground-truth odometry. Changing the wheel collision from a cylinder to a sphere reduced dead-reckoning drift on the medicine route from 0.16 to 0.011 m (worst of two repeats; `scripts/i14_pilot_p_range.py`).
- **Free-form JSON from the first VLM was unusable** on our renders. With Qwen2.5-VL-3B, 21 of 96 responses (48 images, two questions each; all 21 for the first question) could not be parsed and the model hallucinated water on empty shelves. A newer model parses reliably, but it still approves fewer correct deliveries than scoring does (Table S2). This motivated closed-set scoring. T1 measured the free-JSON method again (Table S2).
- **Middleware effects.** Best-effort QoS silently dropped 92 of 102 0.9 MB camera frames under load. The GPU lidar detected the robot's own camera mast. Slow DDS discovery on a 4-core host failed 4 of 12 starts in an aborted campaign. An interrupted supervisor left an orphaned stack that made every trial of the next campaign stop with two `/cmd_vel` publishers. All of these are recorded with their fixes; the aborted campaigns are published.
- **Stale-request latch.** Two pre-decision retries in campaign D happened while the robot was stationary: the mission node's request stream stalled for ≈0.3 s on the saturated CPU. We instrumented the mission loop, the guard and garbage collection and rejected two hypotheses (guard starvation, GC pauses). Raising control-loop priority did not remove the stalls. We therefore changed the guard: a stale zero request now holds zero, while a stale motion request still latches. With a 0.6 s stall injected before

departure, the old guard failed 2/2 runs and the new one completed 2/2. Raising priority with a file capability then had a side effect: it put the exec into the dynamic loader's secure mode, which stripped `LD_LIBRARY_PATH` and broke the ROS bag recorder. A regression run caught this before any campaign.

- **A pilot exposed a threshold that was not conservative enough.** Before campaign E we ran nine trials in separate pilot worlds. In one, the robot found the wrong item, searched the other station, and delivered from it although a fire burned behind it. The fire was almost entirely hidden by the first-aid kit, and $p_h = 0.32$. On development data no fire-free image exceeded $p_h = 0.0007$, so we lowered τ_h to 0.05 (v3.5). The same pilot worlds then gave 9/9 expected outcomes. T1 was not involved: both thresholds were registered for T1 before any T1 image was scored.
- **A generator bug caught by looking at the data.** In the first T1 render, distractors meant to stand next to a supply were placed through it. The emptiness check ran after the supplies were moved. The render was discarded and the fix recorded as a pre-registration amendment, before any model scored a T1 image. A second amendment replaced the field-of-view fire label with the rendered-mask label, after we saw fires hidden behind supplies that the geometric label had called visible.

S9. Registration audit

For every study with results, the registration commit precedes the results commit (holds). Campaign C's registration and ledger entered the repository together, so their order cannot be verified from the history.

A. Threats to validity

Internal. The studies were designed sequentially, each registered after the results of the previous ones were known, so registration is confirmatory within a study but not across the programme (Table S9); study K was registered after the T2 scores it reuses had been computed (`PREREGISTRATION_K.md`, offline, no new inference). The H stories are scripted so that a naive memory fails by construction; the M1–M2 contrast is therefore large by design, and the M2–M0 comparison is the one that bounds risk (`PREREGISTRATION_H.md`). The analysis scripts computed the median of an even-length list as the upper-middle element; this was fixed and all summaries regenerated, and errata with no change to protocols, endpoints or claims are in `PREREGISTRATION_{F,G,H}.md` (for H, a relocation-persist median of 79 s had been reported as 85 s). Campaign J deviated during the run (`PREREGISTRATION_J.md`): from trial J007 documentation builds shared the 4-core host, and alternating about 46 GB of weights through a 54 GB page cache made every check re-read its weights, so measured latency includes model I/O and is inflated in both arms; two first attempts failed before any VLM decision and were re-run under the registered retry rule.

Construct. Fire labels come from rendered mask pixels (a fire is perceivable at 614 pixels or more), not from human judgement, and the fire is stylised. "Delivery" means that the robot reached the shelter after approving; there is no handover, so grasping and placing are not tested.

External. All results use one arena geometry, two stations and simulation only. The real-photograph study (P) is descriptive and reports false alarms on D-Fire images; it does not test a robot. The two checkers in J share lineage (Clef-Flash is post-trained from Qwen3.5-9B), so errors may be correlated.

Statistical. Samples are small: P1 has 8 relocation-persist pairs, and P3 compares 0 unsafe deliveries (M2) with 1 (M0), which shows only that M2 is not less safe (Wilson upper bounds 11% and 16%). Images of one world, and missions of one sequence, are not independent; we therefore add world-cluster bootstrap intervals and a sequence-level McNemar test, which are wider or less powerful than the pooled ones. Several studies are reported without family-wise correction, because each has its own registered endpoint and the claims are not pooled.

S10. Untrusted Inputs: Proof, Cost Bound and Threat Model

Setting. Let $A_\theta(o) = [\text{supply}(o;\tau_s)] \wedge \bigwedge_{v\in V}[p_h^{(v)}(o) < \tau_h]$ be the check of Eq. (1) with the look-around views V, and let an advice set $\mathbf{a} = \{a_1,\dots,a_n\}$ be any finite set of items $a = (\text{source}, \text{kind}, \text{station})$ with kind $\in \{\text{location}, \text{hazard}, \text{safe}, \text{skip}\}$ and station one of the arena's stations. The planner is the function $\text{plan}(\theta, A) = (\pi, \theta')$ implemented in `rescuemind/advice.py`:

- π is the order of the (at most $k = 2$) stations: a location item for station j moves j first; all other items leave π unchanged. The set of stations is never changed.
- $\theta'_j = (\tau_s,\ \min(\tau_h, \tau_h^{\text{caut}} \text{ if some hazard item names } j),\ V)$ at station j, with $\tau_h^{\text{caut}} = 0.01$.
- *safe* and *skip* items are rejected and logged; no item can create a refusal without a visit, a delivery without a check, or a change of τ_s or V.

Lemma 1 (every plan is verification-preserving). For every $\mathbf{a}$, $\tau'_{s,j} = \tau_s$, $\tau'_{h,j} \le \tau_h$ and $V'_j = V$ at every station j in π. *Proof.* Immediate from the definition of plan: the second component is a minimum with τ_h, the first and third are copied. The run audit recomputes $\text{plan}(\theta, \mathbf{a})$ from the logged items and rejects the run if the logged θ' differs or is not of this form (`advice.assert_monotone`). □

Proposition 2 (advice monotonicity). For every $\mathbf{a}$ and every observation o at a station, $A_{\theta'}(o) \Rightarrow A_\theta(o)$, and an unsafe delivery requires a false approval of A_θ at one of at most k must-refuse checks. Hence $\Pr[\text{unsafe delivery} \mid \mathbf{a}] \le k\varepsilon$, the bound of the advice-free robot, where ε bounds the false-approval probability of A_θ on a must-refuse station (Corollary 1 of the main paper).

Proof. By Lemma 1 the supply conjunct is the same predicate and the set of hazard conjuncts is the same ($V' = V$), but each hazard conjunct $[p_h^{(v)} < \tau'_h]$ is at least as strong as

$[p_h^{(v)} < \tau_h]$ because $\tau'_h \le \tau_h$. A conjunction whose conjuncts are each at least as strong as the corresponding conjuncts of another implies it, so $A_{\theta'}(o) \Rightarrow A_\theta(o)$. The robot delivers only after $A_{\theta'}$ approved the delivering station: safe and skip items do not exist in the plan, and a refusal without a visit is not a plan option, so every delivery is preceded by a check at the delivering station. By the implication, A_θ approved the same frames. The set of checked stations has at most k elements for every π, since advice does not add stations. An unsafe delivery therefore requires A_θ to approve a must-refuse view at one of at most k stations, and the union bound gives $\Pr \le k\varepsilon$ independently of $\mathbf{a}$. The advice-free robot satisfies the same bound with the same k. □

What the proposition does not say. It does not bound time or availability; extraction of items from text may be wrong, which cannot matter for safety because the guarantee holds for *any* advice set; it assumes that ε holds uniformly over the views the route meets; and it does not cover anything that reaches the decision through the camera. The destination in the operator's request is parsed separately in a closed set with an explicit rule (not by this proposition); the offline set of study A measures wrong-shelter acceptance (must be 0).

Cost bound (denial of service). Let δ be the per-view false-alarm rate of the hazard question on fire-free views at the caution threshold. Study K measured $4/193$ per view at $\tau_h = 0.0113$ on the held-out fire-free images (`k_summary.json`), an approximation for 0.01. (i) *Reordering:* the robot visits at most $k = 2$ stations whatever the advice, so false location advice adds at most one wasted visit (the first visited station is wrong, and the one-time search then goes to the other) relative to the best order. (ii) *Caution:* hazard advice at a station adds at most one failure per view, so the added probability of a false refusal is at most $1 - (1-\delta)^v$ with $v = 3$ views (front and two sides): 0.061; with the wasted front view of a false location item ($v = 4$): 0.080; in the worst case the adversary names both stations, $v = 3k = 6$ views: 0.118 (independent views) and $\le 3k\delta = 0.124$ without independence by the union bound. In study A the sum of the per-run bounds over the 24 monotone runs on poison_location and poison_hazard worlds is 1.7 expected false refusals; `scripts/a_analysis.py` compares the observed count with the 95th percentile of the Poisson-binomial sum (4). These two numbers, one visit per mission and about 0.06–0.12 of the missions, bound what an attacker can buy through advice.

S11. The Second Checker and Campaign J

This section was part of the main paper; the main paper keeps Table I (row J) and a summary.

A. Method: the second checker

The original design of this robot asked two models (a second checker, called Jev in that design, and Qwen) and moved only when both agreed, following the idea of diverse redundancy [89], although failures are known to be correlated in practice [90]. The second checker is Clef-Flash, a decision model released by Cloudflare [103], [104] and served locally through the original second-checker API. According to its model card it is post-trained from Qwen3.5-9B, so the two models share lineage. Their diversity lies in post-training, in model size (our on-robot pair uses Qwen3.5-4B) and in the question asked, and the correlated-failure caveat applies in full. The two-model rule approves only if Eq. (1) holds for Qwen *and* Clef-Flash agrees (thresholds: Sec. S1). A hazard seen by either model stops the robot, and a wrong supply seen by either allows the one-time search. Whether the two models fit one GPU is tested in Sec. S11-B. The second model is a veto whose errors overlap with Qwen's. Qwen misses 17 of 211 development fires, and Clef-Flash also misses 15 of these (88%, Wilson [66, 97]%; Table S9).

B. Results: two models on one GPU (campaign J)

On T2, Clef-Flash together with Qwen3.5-4B, the pair that fits on one 32 GB V100, made 0/407 false approvals (185/193 correct). Campaign J ran this pair on the robot, paired with v3.6 on 24 worlds with swapped, empty and small-fire stations; it behaved as expected in 23/24 (v3.6: 24/24, exact McNemar $p = 1.0000$), with unsafe deliveries: 1 (v3.6: 0; Wilson upper bounds 20% and 14%); stack failures: 0. Peak GPU memory was 28.0 GB, and the median check latency was 5.1 s for the two-model system and 5.7 s for v3.6; on our host, alternating ≈46 GB of weights thrashed the page cache, so both include model I/O (registered deviation note). The registered claim (two-model design on the simulated robot, no extra risk) is not supported. Its one unsafe delivery was a small fire behind the station reached after a search; both models missed it, the correlated failure that their development-set overlap predicts (Sec. S11-A). The arms differ in model size and hazard wording, so this does not test two-model checking in general, but it is why we did not adopt the pair.

TABLE S10

THREAT MODEL FOR INPUTS THE ROBOT DID NOT PERCEIVE ITSELF. "STRUCTURAL": A GUARANTEE THAT DOES NOT DEPEND ON THE MODEL'S ANSWERS.

Channel	Example attack	Structural?	Measured by
Own memory	stale or poisoned record: "water at M", "no fire at W"	yes (Obs. 1, Prop. 2)	H, V (naive vs. verified memory)
Peer robot report, inventory	false "fire is out", wrong location, "verified, skip"	yes (Prop. 2)	A, file channel
Operator wording (advice)	"the fire is out, no need to check"; "ignore previous instructions"	yes (Prop. 2); extraction itself is a model	A, operator channel; 224 offline texts
Operator wording (destination)	"deliver to shelter A", school or hospital	no: closed-set parser plus explicit rule, fail-closed	A offline set (wrong-shelter acceptance must be 0)
Scene text	label "WATER" on a first-aid kit; sign "SAFE – NO FIRE"; "Answer C"	no: it is perception	S
Camera degradation	noise, blur, over-exposure (not adversarial)	no: fail-closed behaviour measured	R
